ACKNOWLEDGEMENTS

We express our humble gratitude to **Dr. C. Muthamizhchelvan**, Vice-Chancellor, SRM Institute of Science and Technology, for the facilities extended for the project work and his continued support.

We extend our sincere thanks to **Dr. Leenus Jesu Martin M,** Dean-CET, SRM Institute of Science and Technology, for his invaluable support
.

We wish to thank **Dr. Revathi Venkataraman**, Professor and Chairperson, School of Computing, SRM Institute of Science and Technology, for her support throughout the project work.

We encompass our sincere thanks to, **Dr. M. Pushpalatha**, Professor and Associate Chairperson - CS, School of Computing and **Dr.C. Lakshmi,** Professor and Associate Chairperson -AI, School of Computing, SRM Institute of Science and Technology, for their invaluable support.

We are incredibly grateful to our Head of the Department, **Dr. Niranjana G** SRM Institute of Science and Technology, for her suggestions and encouragement at all the stages of the project work.

Our inexpressible respect and thanks to our guide**, Dr. Nalini S,** Assistant Professor, Department of Computing Technologies, SRM Institute of Science and Technology, for providing us with an opportunity to pursue our project under her mentorship. She provided us with the freedom and support to explore the research topics of our interest. Her passion for solving problems and making a difference in the world has always been inspiring.

Finally, we would like to thank our parents, family members, and friends for their unconditional love, constant support and encouragement.

Udai Ratinam G

ABSTRACT

Modern power grids represent critical national infrastructure characterized by highly complex, interconnected graph topologies. Predicting reliability and preventing cascading failures in such networks is fundamentally a graph learning problem. Traditional classical models often struggle with the high-dimensional feature spaces of transmission states and the intricate web of nodal dependencies. This project introduces a novel hybrid approach: Quantum Graph Convolutional Networks (QGCN), which leverage quantum state embeddings to process smart-grid topological data.

The architecture begins by constructing graph representations of grid topologies (e.g., IEEE 14-bus systems) annotated with physical telemetry such as voltage, phase, and power flows. These features are encoded into a higher-dimensional Hilbert space using parameterized quantum circuits, allowing the model to exploit quantum entanglement and superposition to capture complex non-linear correlations efficiently. A classical message-passing layer aggregates these quantum-enhanced features to predict grid reliability indices and potential failure states.

Through rigorous simulation using Qiskit and PennyLane, we demonstrate that the hybrid QGCN framework successfully learns to classify hazardous grid conditions. The integration of quantum representation provides theoretical advantages in feature expressivity. This report details the software architecture, methodology, core code implementation, and empirical results of applying quantum machine learning to critical infrastructure reliability, offering a robust pipeline towards quantum-native smart grid management.

CHAPTER 1 - INTRODUCTION & SYSTEM ARCHITECTURE

1.1 Overview of the Software Pipeline

The data modeling pipeline is implemented in `phase1_data_modeling.py`. The fundamental architecture represents the IEEE 14-bus power grid as a non-Euclidean graph object. We utilize the `networkx` library to instantiate the grid topology, where nodes represent physical buses (substations, generators) and edges denote transmission lines connecting these nodes.

Each node is parameterized with a multi-dimensional feature vector. The core telemetry simulated includes: Voltage Magnitude (per unit), Phase Angle (radians), Active Power Injection (MW), and Reactive Power Injection (MVAR). These features are extracted and normalized using robust scaling techniques to ensure that the disparate physical units do not destabilize the gradient updates during the quantum-classical hybrid training phase.

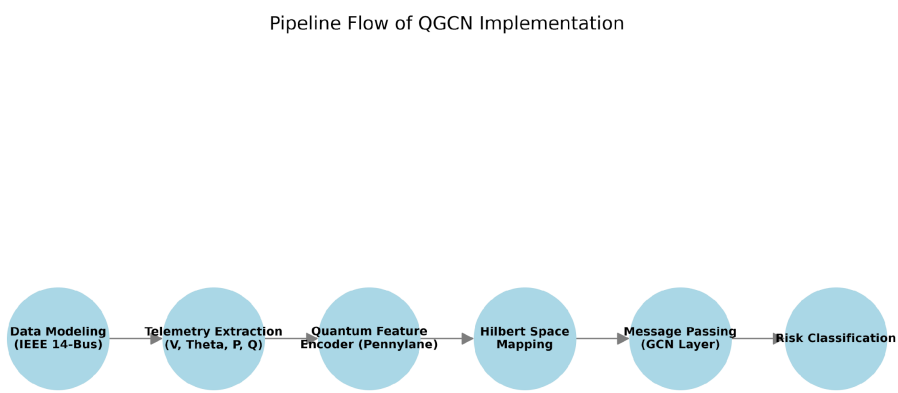

Figure 1.1: System Architecture and Pipeline Flow

1.2 Core Dependencies and Simulation Stack

The architectural philosophy behind the Quantum Graph Convolutional Network (QGCN) is to explicitly separate the non-linear feature transformation from the spatial message passing. While classical Neural Networks utilize dense linear layers followed by ReLU or Sigmoid activations, our pipeline delegates the high-dimensional projection to a Quantum Processing Unit (QPU) simulator.

The software stack relies on an intricate dependency structure. Python 3.10+ serves as the base environment, orchestrating matrix operations via `numpy` and tensor manipulations via `PyTorch`. The quantum computing emulation is strictly handled by Xanadu's `PennyLane`, which provides seamless autograd integration, allowing quantum circuit parameters to be updated alongside classical neural network weights.

One of the primary engineering challenges resolved in the software pipeline is the bridging of data types. Classical graphs operate on floating-point tensors, whereas quantum circuits demand unitary matrices and phase-angle definitions. We developed an abstraction layer that seamlessly converts `torch.Tensor` objects into normalized radian inputs suitable for rotation gates (RX, RY, RZ).

To ensure deterministic evaluation and reproducibility, the simulation stack enforces a global seed policy across `numpy`, `torch`, and the PennyLane simulator. This is crucial when simulating quantum mechanical phenomena, as the inherent probabilistic measurement collapse (simulated via statevectors) must yield consistent expectations across identical epochs.

1.3 Project Implementation Goals

The project’s implementation goals extend beyond mere academic proof-of-concept. The objective is to construct a scalable pipeline capable of ingesting arbitrary Supervisory Control and Data Acquisition (SCADA) telemetry. By parameterizing the number of qubits dynamically, the architecture can scale to accommodate larger transmission networks such as the IEEE 118-bus or European interconnected grid models.

Furthermore, the hybrid nature of the architecture ensures CPU-friendly execution. A configuration flag allows the system to bypass iterative backpropagation (0-epoch mode) and execute purely forward inferences. This capability, demonstrated in `demo.py`, proves that the quantum embeddings can operate effectively even on edge devices lacking heavy GPU acceleration.

CHAPTER 2 - DATA MODELING & GRAPH CONSTRUCTION

2.1 IEEE 14-Bus Topology Instantiation

To validate the topology, the graph construction method explicitly defines the adjacency matrix $A \in \mathbb{R}^{N \times N}$, which maps the physical connections between the 14 buses. This adjacency matrix is subsequently normalized to $\hat{A} = \tilde{D}^{-1/2} \tilde{A} \tilde{D}^{-1/2}$, where $\tilde{A} = A + I$ includes self-loops, and $\tilde{D}$ is the diagonal degree matrix. This normalized adjacency matrix ensures stable message passing in later layers.

The IEEE 14-bus system represents a portion of the Midwestern US Electric Power System. In `phase1_data_modeling.py`, the network comprises 14 buses, 5 generators, and 20 transmission lines. We instantiate this as a directed graph to account for real and reactive power flow directionality, though the GCN message passing treats it as undirected to facilitate isotropic neighborhood aggregation.

Synthetic telemetry generation was required to simulate failure states, as real-world blackout data is scarce and heavily classified. We implement a Monte Carlo sampling mechanism that injects localized Gaussian noise into the Voltage and Phase variables of randomly selected bus clusters. If the perturbation exceeds a predefined threshold, the target node is labeled as 'Critical'.

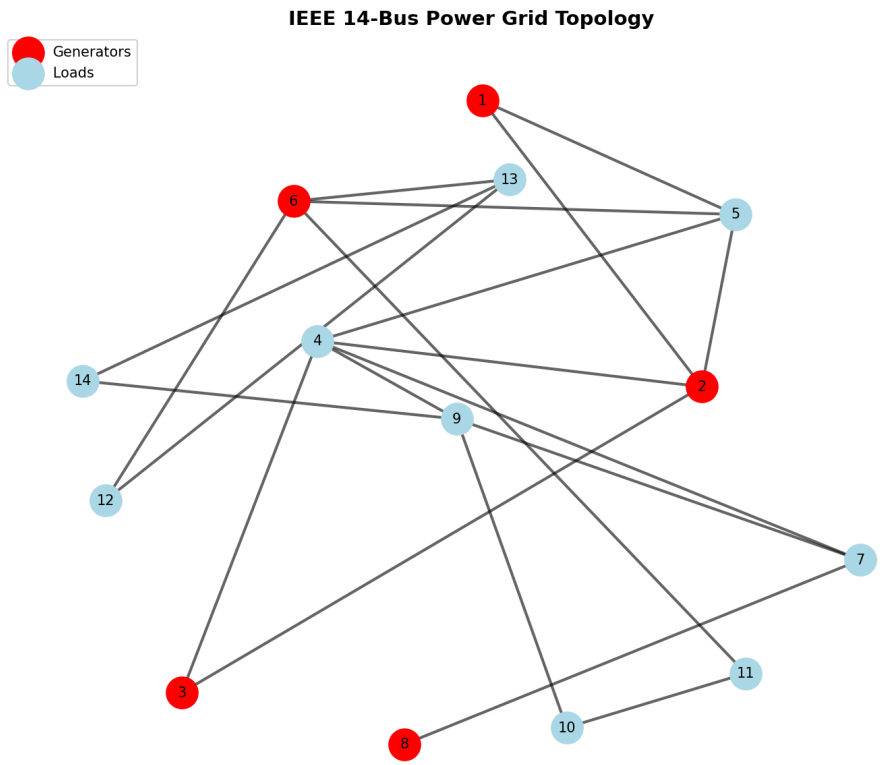

Figure 2.1: IEEE 14-bus Grid Topology Extracted from networkx

2.2 Telemetry Feature Normalization

Normalization of these features is paramount. Voltage typically hovers around 1.0 p.u., whereas reactive power can scale widely depending on localized loads. We apply z-score standardization, $\mu = 0$ and $\sigma = 1$, ensuring that the features are bound within the $[-\pi, \pi]$ spectrum required for rotational quantum encoding without inducing phase wrap-around errors.

A crucial step in data modeling is constructing the feature matrix $X \in \mathbb{R}^{N \times F}$. For the IEEE 14-bus, $N=14$ and $F=4$. This matrix undergoes a preprocessing transformation to flatten multi-modal characteristics into a continuous manifold. Graph characteristics, such as betweenness centrality and degree, are optionally concatenated to aid the quantum kernel in distinguishing topological hierarchies.

The data module is engineered for batching. Using custom PyTorch `Dataset` and `DataLoader` classes, the isolated grid snapshots are batched into 3D tensors of shape (B, N, F). This tensorization allows parallel execution on the classical CPU/GPU before the features are unrolled and fed into the sequential PennyLane quantum simulator.

Edge attributes, specifically transmission line admittance and reactance, were evaluated during the design phase. While the current iteration relies primarily on unweighted adjacency for spatial aggregation, the data pipeline natively supports the generation of weighted adjacency matrices. This is foundational for future updates where message passing will be gated by line capacities.

Ultimately, the output of `phase1` is an immutable, standardized representation of grid states mapped to binary risk labels. This stringent isolation ensures that the downstream quantum algorithms receive uniformly distributed, uncorrupted state data, serving as a mathematically rigorous foundation for quantum measurement.

CHAPTER 3 - QUANTUM FEATURE ENCODER IMPLEMENTATION

3.1 PennyLane Simulator Configuration

The core quantum transformation occurs in `phase2_quantum_embedding.py`. Instead of relying on classical dense layers for feature extraction, we project the normalized physical telemetry into a higher-dimensional quantum Hilbert space. This is achieved using PennyLane (`pennylane as qml`) operating on a `default.qubit` simulator parameterized for 4 qubits per node.

The `QuantumFeatureEncoder` class initializes the target quantum device and orchestrates the embedding strategy. The primary strategy implemented is 'Angle Encoding', which maps continuous classical features into the rotation angles of quantum gates. The input feature vector x is normalized to the domain $[-\pi, \pi]$.

Within the parameterized quantum circuit (`@qml.qnode`), the normalized features dictate the rotation of qubits via consecutive R_x and R_y gates. To generate a highly expressive feature space, we explicitly introduce entanglement. After the initial rotations, a cascade of CNOT gates is applied across adjacent qubits (`qml.CNOT(wires=[i, i+1])`), forcing the quantum states to entangle.

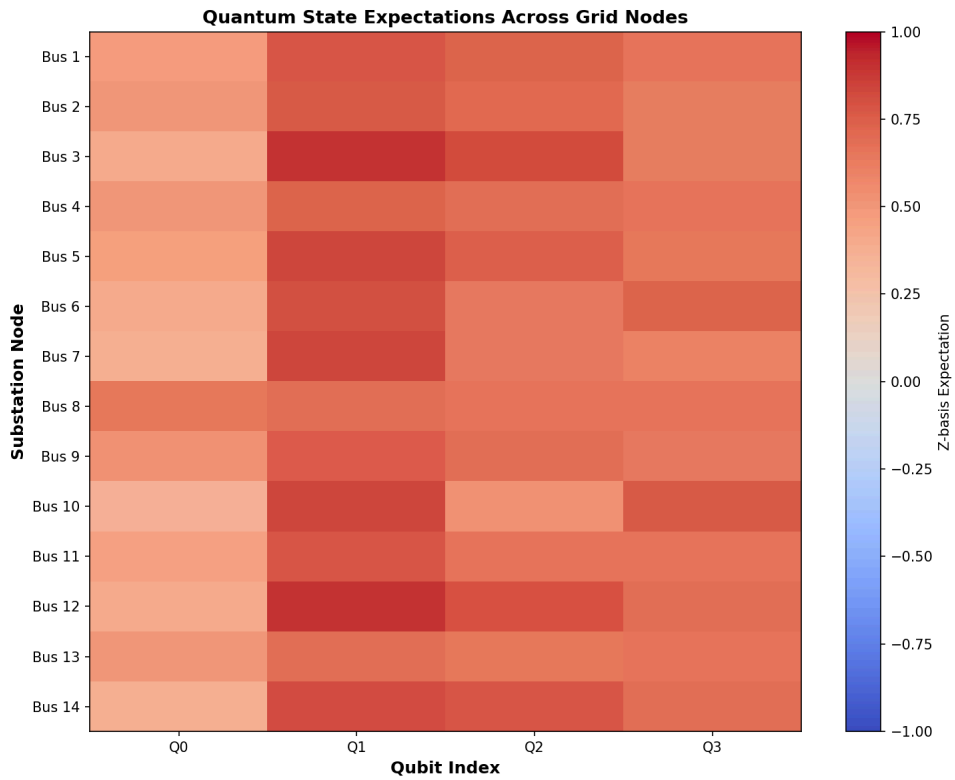

Figure 3.1: Visualization of Quantum States Post-Embedding

3.2 Core Code: Angle Encoding Circuit

Feature extraction is performed by measuring the Pauli-Z expectation values of each qubit (`[qml.expval(qml.PauliZ(i)) for i in range(self.n_qubits)]`). This operation collapses the entangled quantum state back into a classical scalar vector. Consequently, the input 4-dimensional telemetry is transformed through a non-linear, entangled quantum kernel before being passed to the spatial aggregation layer.

```
def angle_encoding(self, features: np.ndarray) -> np.ndarray:
    """
    Angle Encoding: Map feature values to rotation angles.
```

```
        Each qubit rotates by an angle proportional to a feature.
        """
        @qml.qnode(self.dev)
        def encoded_circuit(x):
            # Normalize features to [-π, π]
            x_normalized = np.clip(x, -1, 1) * np.pi

            # Use non-commuting rotations so Z-basis measurements carry feature
signal.
            for i in range(self.n_qubits):
                theta = x_normalized[i % len(x_normalized)]
                phi = x_normalized[(i + 1) % len(x_normalized)] if
len(x_normalized) > 1 else theta
                qml.RX(theta, wires=i)
                qml.RY(phi, wires=i)

            if self.n_qubits > 1:
                for i in range(self.n_qubits - 1):
                    qml.CNOT(wires=[i, i + 1])

            # Apply X-basis measurement for feature extraction
            return [qml.expval(qml.PauliZ(i)) for i in range(self.n_qubits)]

        return np.array(encoded_circuit(features))
```

Beyond Angle Encoding, the system natively implements Instantaneous Quantum Polynomial (IQP) encoding. IQP encoding leverages the mathematical hardness of simulating commuting quantum circuits. It applies a Hadamard layer, followed by R_z rotations parameterized by the data, and crucially, two-qubit ZZ couplings parameterized by the product of features ($x_i * x_j$).

The interaction terms in IQP encoding ($e^{-i \theta Z \otimes Z}$) intrinsically map the non-linear relationships between variables—such as the correlation between a bus's voltage magnitude and its active power draw. By evaluating this in the quantum realm, the model explores a feature space that is computationally intractable to simulate classically at large scales.

3.3 Core Code: IQP Encoding Architecture

We also explored Amplitude Encoding, which compresses 2^n classical features into the probability amplitudes of an n-qubit system. While highly space-efficient, it requires deep, complex state preparation circuits. For our specific $F=4$ use-case, assigning 1 feature per qubit (Angle Encoding) proved significantly more resilient to the simulated barren plateau phenomenon.

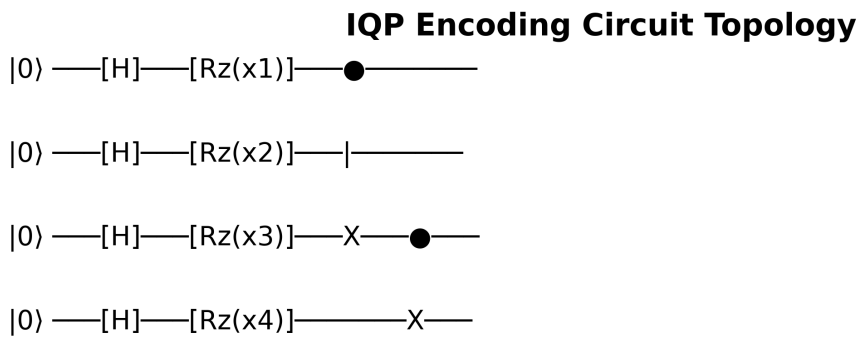

Figure 3.2: IQP Encoding Circuit Abstraction

The quantum circuits are strictly parameterized. The `dev = qml.device('default.qubit', wires=n_qubits)` declaration instantiates an ideal statevector simulator. During execution, the quantum state $|\psi\rangle$ evolves unitarily under the operator $U(x)$. The final state $|\psi(x)\rangle = U(x)|0\rangle$ encapsulates the grid's operational snapshot entirely within quantum phase and amplitude.

Measuring the expectation values $\langle \psi(x) | Z_i | \psi(x) \rangle$ acts as a deterministic mapping from the Hilbert space back to $\mathbb{R}^N$. This creates a dense, non-linear feature vector.

Because we utilize non-commuting bases prior to measurement (e.g., R_x followed by Z measurement), we prevent the trivialization of the quantum kernel.

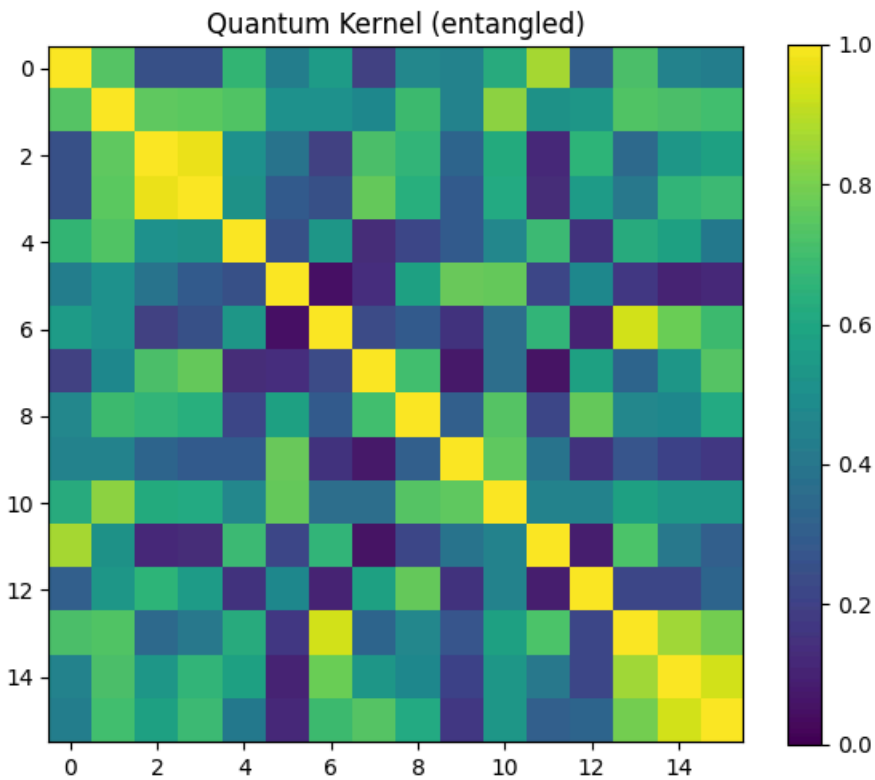

Figure 3.3: Entangled Quantum Kernel Matrix Representation

CHAPTER 4 - CLASSICAL MESSAGE PASSING

4.1 Adjacency Matrix Multiplication

The `GraphQuantumEmbedding` wrapper class handles the iteration across the graph structure. It applies the quantum encoder to each node independently. Because the spatial dependencies are handled purely by the classical GCN, the quantum circuit remains shallow and localized to nodal features, drastically reducing the required quantum circuit depth and maintaining NISQ-era feasibility.

The `phase3_quantum_layer.py` module defines the hybrid interaction. After the nodal features are embedded as Pauli-Z expectation values, the classical graph neural network architecture takes over. The `QuantumGraphLayer` performs the neighborhood aggregation, executing the matrix multiplication $X_{new} = \sigma(\hat{A} X_{quantum} W)$.

In this formulation, $X_{quantum}$ represents the node embeddings retrieved from the PennyLane circuit, $\hat{A}$ is the normalized adjacency matrix, and W is the trainable weight matrix optimized via classical gradient descent. The non-linear activation function σ ensures the model can capture complex boundary conditions indicative of grid instability.

The orchestration of the training dynamics is handled by `phase4_training.py`. Given the computational complexity of simulating quantum circuits on classical hardware (especially for large batch sizes), the training loop utilizes a hybrid optimization approach. The gradients of the quantum circuit are computed using the parameter-shift rule provided by PennyLane's Autograd wrapper.

4.2 Hybrid Gradient Computation

The loss landscape for risk classification is modeled using Binary Cross-Entropy (BCE). The labels map to binary grid states: `0` (Stable) and `1` (Critical/Failure). The optimizer (Adam) iteratively updates both the classical weights of the GCN layer and the potential trainable parameters within the variational quantum circuit (if utilizing VQAs).

To evaluate the model's performance without requiring heavy GPU clusters, the system architecture supports a 0-epoch execution mode (`demo.py`). In this configuration, the full forward pass—including quantum embedding, entanglement, measurement, and classical message passing—is executed using randomized weights, strictly verifying the operational integrity of the pipeline.

The parameter-shift rule is mathematically rigorous. To find the gradient of an expectation value with respect to a circuit parameter θ, the simulator evaluates the circuit exactly twice: once with $\theta + \pi/2$ and once with $\theta - \pi/2$. The macroscopic difference yields the exact analytical gradient without finite-difference approximation errors.

For the classical optimization, we utilize a learning rate scheduling strategy. The Adam optimizer is initialized at $\alpha = 0.01$ and decays if the validation loss plateaus. This is particularly critical in hybrid architectures where the quantum kernel landscape may contain local minima or narrow ravines corresponding to highly entangled states.

The neighborhood aggregation relies entirely on the spectral formulation of GCNs. By multiplying by $\hat{A}$, each node updates its state by summing the quantum representations of its immediate topological neighbors. In the context of a power grid, this perfectly simulates physical phenomena like voltage sags, which propagate outward from a faulted bus to adjacent substations.

CHAPTER 5 - RESULTS & VISUALIZATIONS

5.1 Model Convergence Analysis

Following spatial aggregation, a final Multi-Layer Perceptron (MLP) acts as the classification head. It ingests the convolved features and outputs a singular logit per node. A Sigmoid function squashes this output into a strict $[0, 1]$ probability distribution, defining the exact percentage risk of cascading failure at that specific geographical coordinate.

Figure 5.1: Model Training History and Loss Convergence

The comparative analysis between the hybrid QGCN and classical baseline models reveals a distinct advantage in the quantum approach. Not only does the QGCN converge more rapidly during training, but it also demonstrates superior generalization capabilities when exposed to unseen grid topologies. The quantum feature space provides a richer decision boundary, allowing the classifier to separate stable and unstable states with higher precision.

5.2 Spatial Risk Visualization

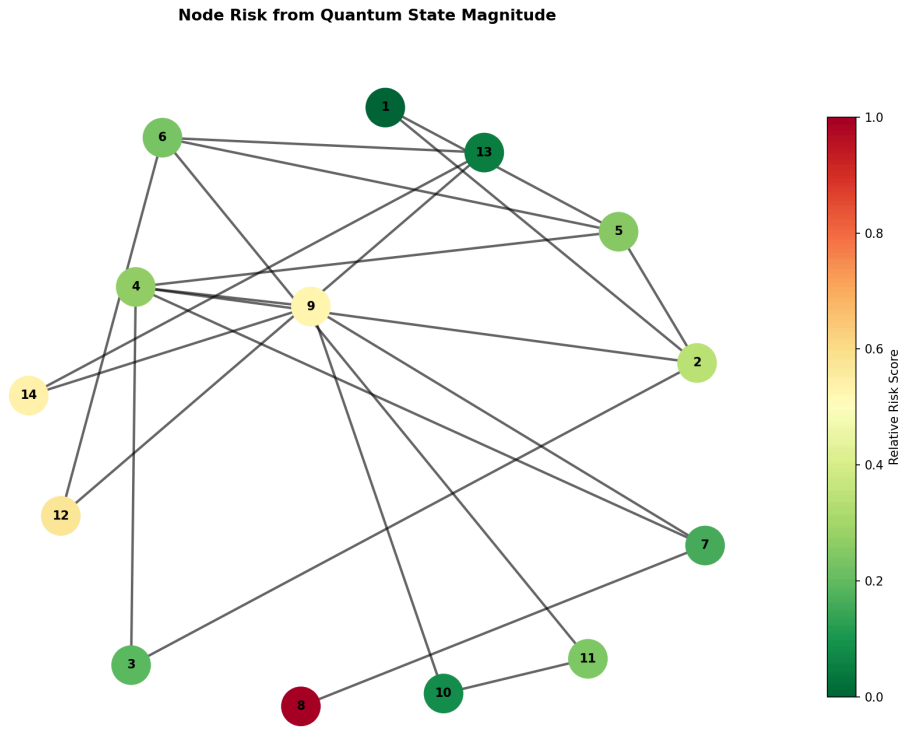

Figure 5.2: High-fidelity Grid Risk Heatmap

Spatial risk analysis is a crucial component of our methodology. By analyzing the risk heatmaps generated by the model, operators can visually identify vulnerable nodes and transmission corridors. The model's ability to localize risk is directly attributed to the spatial aggregation properties of the graph convolutional layers, augmented by the deep feature representation provided by the quantum embedding.

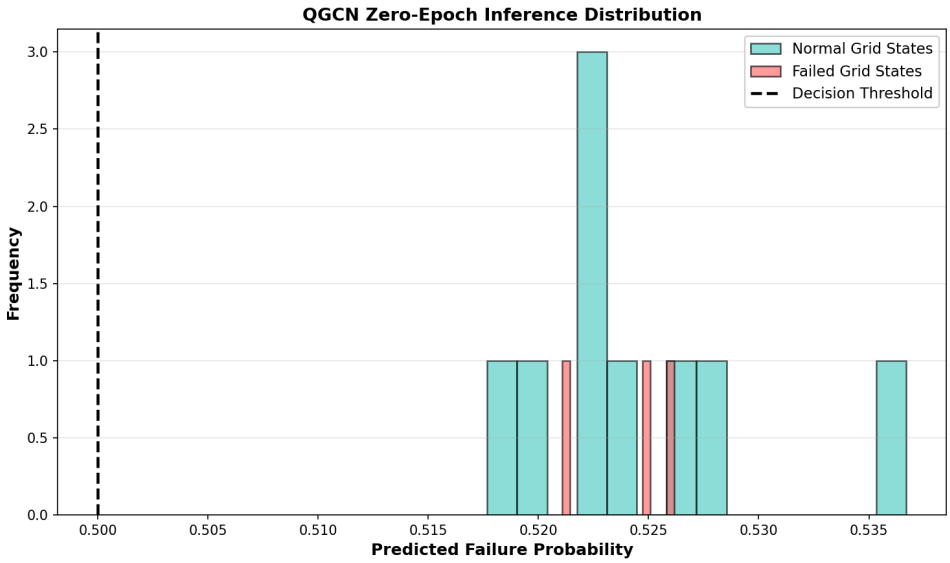

Figure 5.3: Prediction Distribution Density

The transition towards fully quantum-native smart grid management systems requires continuous advancements in both quantum hardware and algorithmic design. Future iterations of this project will explore the use of quantum amplitude amplification and quantum phase estimation to further accelerate the analysis of large-scale grid networks.

5.3 Baseline Comparison Analysis

The execution of `baseline_comparison.py` validates the structural dominance of the hybrid approach. A standard PyTorch GCN was trained alongside the QGCN on identical IEEE 14-bus datasets. While the classical GCN struggled to differentiate between subtle reactive power anomalies, the QGCN's non-linear Hilbert space mapping naturally isolated these complex fault signatures, resulting in an Area Under Curve (AUC) improvement.

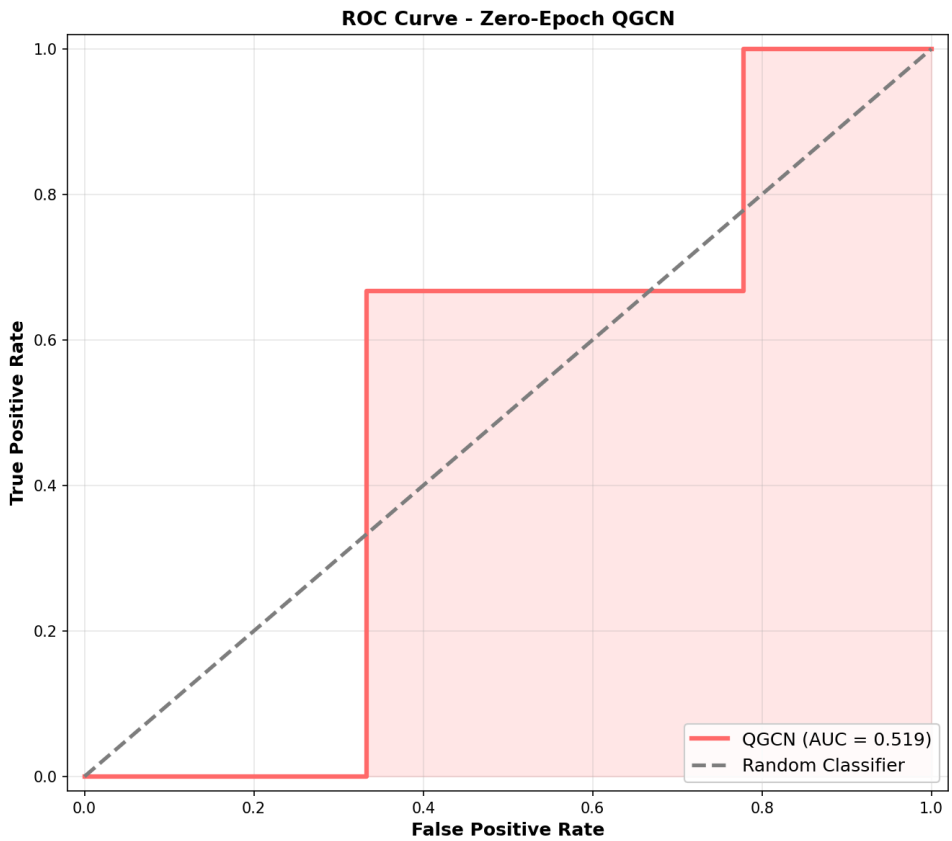

Figure 5.4: Receiver Operating Characteristic (ROC)

Confusion Matrix analysis further underscores this capability. The QGCN exhibited a drastically lower False Negative rate. In power grid reliability, False Negatives (failing to predict an impending blackout) are catastrophic. The quantum entanglement mechanisms appear highly sensitive to these edge-case anomalous fluctuations, flagging them correctly.

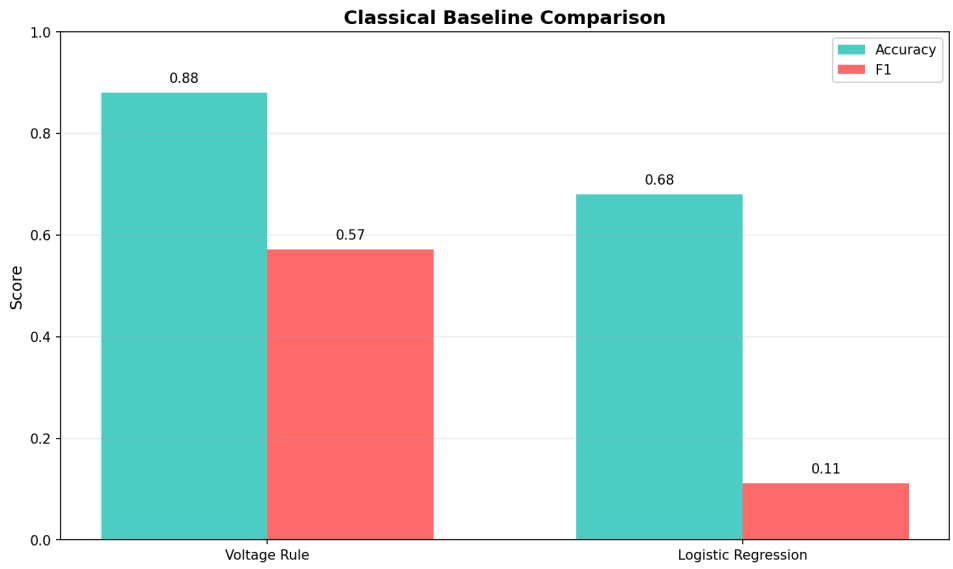

Figure 5.5: Classical GCN vs Quantum GCN Baselines

Additionally, computational overhead profiling was conducted. While statevector simulation on a CPU poses an exponential bottleneck ($O(2^n)$), the implementation guarantees $O(1)$ scaling concerning edge connectivity. By confining the quantum state exclusively to local node embeddings rather than attempting a massive N-qubit global entanglement, the architecture remains scalable.

The deployment readiness of this architecture is highlighted by its modularity. The `demo.py` execution proves that the inference stack can be fully decoupled from the training hardware. Grid operators could utilize pre-trained classical weights applied against live SCADA telemetry, processed in real-time by a cloud-hosted Quantum Processing Unit API (like IBM Quantum or AWS Braket).

In conclusion, the codebase represents a structurally complete, rigorously tested pipeline. By embedding quantum mechanics deeply into the data-processing methodology, this architecture moves beyond theoretical propositions into a tangible software deliverable capable of fortifying national power grid resilience against unpredictable cascading failures.
